Abstract

There are well-known examples of dynamical systems for which the Birkhoff averages with respect to a given observable along some or all of the orbits do not converge. It has been suggested that such orbits could be classified using higher order averages. In the case of a bounded observable, we show that a classical result of G.H. Hardy implies that if the Birkhoff averages do not converge, then neither do the higher order averages.

If the Birkhoff averages do not converge then we may denote by $[\alpha_k, \beta_k]$ the limit set of the k -th order averages. The sequence of intervals thus generated is nested: $[\alpha_{k+1}, \beta_{k+1}] \subset [\alpha_k, \beta_k]$. We can thus make a distinction among nonconvergent Birkhoff averages; either:

B1. $\cap_{k=1}^{\infty} [\alpha_k, \beta_k]$ is a point B_{∞} , or,

B2. $\cap_{k=1}^{\infty} [\alpha_k, \beta_k]$ is an interval $[\alpha_{\infty}, \beta_{\infty}]$.

We give characterizations of the types **B1** and **B2** in terms of how slowly they oscillate and we give examples that exhibit both behaviours **B1** and **B2** in the context of full shifts on finite symbols and “Bowen’s example”. For finite full shifts, we show that the set of orbits with type **B2** behaviour has full topological entropy.

1 Birkhoff averages and higher order averages

Let X be a metric space, let f be a continuous map from X into itself and let $\phi : X \rightarrow \mathbb{R}$ be a continuous function (observable). Usually we will assume that ϕ is bounded. Given $x \in X$, denote

Keywords and phrases: non-converging averages, Cesáro means, historical dynamics

AMS Subject Classification: 37A99, 37B10, 37C29

$x_i = f^i(x)$ and consider the sequence of partial means:

$$B_n(x) \equiv \frac{1}{n} \sum_{i=0}^{n-1} \phi(x_i). \quad (1.1)$$

The limit of this sequence, if it exists, is called the Birkhoff average of ϕ along the orbit $\{x_i\}$. We can also consider averages along orbits of continuous flows on X in the obvious way. The limit (1.1) need not exist, in which case the limit set of the sequence $\{B_n\}$ is a closed interval in $\mathbb{R}$ which we will denote by $[\alpha_0, \beta_0]$. Such orbits have been labelled *historical* [10].

There are well-known examples of dynamical systems with orbits whose Birkhoff averages do not exist. Among them are “Bowen’s example” and full shifts on finite symbols, both of which we will describe later. In Bowen’s example there is an open set of initial conditions for which the average does not converge [9]. For full shifts, the set of orbits for which the Birkhoff average does not converge has full Hausdorff dimension [2].

It has been proposed that in order to study cases where the average does not converge, one might consider the higher order averages [3, p. 11]. (See the next section for definitions.) It is suggested that they might provide a stratification of dynamical systems or orbits of such, indicating their statistical complexity. However, we find as a corollary to a result by Hardy [5] that if $\phi(x_i)$ is bounded, then the higher-order averages are convergent if and only if the Birkhoff partial averages $\{B_n\}$ converge. Thus, if $\phi(x_i)$ is bounded then either

- A. The Birkhoff average exists, or**
- B. The averages of all orders diverge.**

In other words, a stratification by higher order means does not exist for the case of bounded observables.

There is however a possible distinction among dynamical systems or orbits of class **B** (historical) which we now describe. In case **B** we denote by $[\alpha_k, \beta_k]$ the limit set of k -th order averages. It follows easily that the sequence of intervals thus generated is nested:

$$[\alpha_{k+1}, \beta_{k+1}] \subset [\alpha_k, \beta_k].$$

Therefore, either

- B1.** $\cap_{k=1}^{\infty} [\alpha_k, \beta_k]$ is a point $\bar{B}_{\infty}$, or,
- B2.** $\cap_{k=1}^{\infty} [\alpha_k, \beta_k]$ is a non-trivial interval $[\alpha_{\infty}, \beta_{\infty}]$.

We will give examples that exhibit both behaviours **B1** and **B2**. Specifically, we will show that a full shift on finite symbols has orbits of each type. In fact, for any finite full shift, we show that the set of orbits with type **B2** behaviour has full topological entropy. We will show that all the orbits in Bowen’s example are of type **B1**, while in a non-hyperbolic modification of the example all orbits are of type **B2**.

2 Cesáro and Hölder Means and Slowly Oscillating Series

We begin with the Cesáro means. Suppose $\{a_n\}$ is a sequence of real numbers and denote

$$\begin{aligned} S_n &= a_1 + a_2 + \dots + a_n \\ S_n^{(1)} &= S_1 + S_2 + \dots + S_n \\ \vdots &= \vdots \\ S_n^{(k)} &= S_1^{(k-1)} + S_2^{(k-1)} + \dots + S_n^{(k-1)} \\ \dots &= \dots + \dots + \dots \end{aligned}$$

We say that $\sum a_n$ is “summable by Cesáro mean of the k -th order”, denoted (C, k) , if

$$C_n^{(k)} \equiv \frac{S_n^{(k)}}{n^k}$$

converges as $n \rightarrow \infty$. In [5] we find the following result.

Theorem 2.1 (Hardy). *If $|na_n| < K$ for all $n \geq 1$, then the series $\sum a_n$ cannot be summable by Cesáro mean of any order unless it is convergent.*

An explanation of this Theorem is that a divergent series under the condition $|na_n| < K$ must oscillate very slowly, and this slow oscillation also occurs in the Cesáro means.

In the context of Birkhoff averages, if we let $a_1 = \phi(x_0)$ and

$$a_n = \frac{1}{n}\phi(x_{n-1}) - \frac{1}{n}B_{n-1}, \quad \text{for } n > 1,$$

and define Cesáro means as above, then we have $S_n(x) = B_n(x)$. Note that if $\{\phi(x_i)\}$ is bounded, then $|na_n| \leq 2 \sup_i |\phi(x_i)|$ and so Hardy’s Theorem has the following consequence in the context of Birkhoff averages.

Corollary 2.2. *Suppose $\phi(x_i)$ is bounded and the Birkhoff average of ϕ along $\{x_i\}$ diverges, then the Cesáro means of all orders of the Birkhoff averages also diverge.*

In [3, p. 11] higher order means by the method of Hölder was suggested. For $\{S_n\}$ as above define

$$H_n^{(1)} = \frac{1}{n} \sum_{i=1}^n S_i,$$

and define recursively

$$H_n^{(k)} = \frac{1}{n} \sum_{i=1}^n H_i^{(k-1)}.$$

The series $\sum a_n$ is said to be *summable by Hölder means* or *summable* (H, k) if the sequence $\{H_n^{(k)}\}$ converges as $n \rightarrow \infty$. Note that $H_n^{(1)} = C_n^{(1)}$, so first order Cesáro and Hölder means coincide. For $k > 1$ the means differ, but the methods of summation are equivalent in the sense that $\sum a_n$ is summable (C, k) if and only if it is summable (H, k) . (This result can be found in [6, §5.8] based on [7] and [8].) Thus the conclusions of Corollary 2.2 also hold for Hölder means of all orders.

Below we will denote $H_n^{(0)} \equiv B_n = S_n$, and, $H_n^{(k)}$, $n \geq 1$ will denote the k -th order Hölder means of B_n .

As pointed out by Hardy, divergent sums with the bound $|na_n| < K$ must oscillate slowly. We give a characterization of the slowness. Suppose that $\{B_n\}$ is divergent, with limit set $[\alpha_0, \beta_0]$. Given any $\epsilon > 0$ the sequence $\{B_n\}$ is infinitely often within ϵ of each of the endpoints α_0 and β_0 . For $\epsilon > 0$, define

$$t_1(\epsilon) = \{\min n \geq 1 : B_n(x) > \beta_0 - \epsilon\},$$

and

$$t_2(\epsilon) = \{\min n > t_1 : B_n(x) < \alpha_0 + \epsilon\}.$$

If ϵ is sufficiently small, we may define a unique sequence $\{t_j\}$ by

$$t_j(\epsilon) = \min n > t_{j-1}(\epsilon) : \begin{cases} B_n > \beta_0 - \epsilon, & \text{if } j \text{ is odd} \\ B_n < \alpha_0 + \epsilon, & \text{if } j \text{ is even} \end{cases}.$$

Proposition 2.3. *Suppose $\phi(x_i)$ is bounded. If $\{B_n(x)\}$ is divergent, then for any sufficiently small $\epsilon > 0$ there exists $d > 1$ such that*

$$\frac{t_{j+1}(\epsilon)}{t_j(\epsilon)} \geq d, \quad \text{for all } j \geq 1.$$

Proof:

We will denote

$$\alpha_{-1} = \liminf_{i \rightarrow \infty} \phi(x_i) \quad \text{and} \quad \beta_{-1} = \limsup_{i \rightarrow \infty} \phi(x_i),$$

Let ϵ be small enough so that $\beta_0 - \epsilon > \alpha_0 + \epsilon$ and assume that n is large enough so that $\alpha_{-1} - \epsilon < \phi(x_i) < \beta_{-1} + \epsilon$ for all $i \geq n$. In the following we drop the dependence of t_j on ϵ .

Suppose j is even so that

$$B_{t_j}(x) < \alpha_0 + \epsilon.$$

We have then that

$$\begin{aligned} B_{t_j+1} &< \frac{1}{t_j+1}(t_j B_{t_j}(x) + \beta_{-1} + \epsilon) \\ &< \frac{t_j}{t_j+1}(\alpha_0 + \epsilon) + \frac{\beta_{-1} + \epsilon}{t_j+1}, \end{aligned}$$

and for any $i \geq 1$,

$$B_{t_j+i} < \frac{t_j}{t_j+i}(\alpha_0 + \epsilon) + \frac{i(\beta_{-1} + \epsilon)}{t_j+i}. \quad (2.1)$$

Since

$$B_{t_{j+1}} > \beta_0 - \epsilon,$$

we must have

$$\frac{1}{t_{j+1}}(t_j(\alpha_0 + \epsilon) + (t_{j+1} - t_j)(\beta_{-1} + \epsilon)) > \beta_0 - \epsilon.$$

Solving we find

$$\frac{t_{j+1}}{t_j} > \frac{\beta_{-1} - \alpha_0}{\beta_{-1} - \beta_0 + 2\epsilon} > 1.$$

Similarly, for j odd we obtain

$$\frac{t_{j+1}}{t_j} > \frac{\beta_0 - \alpha_{-1}}{\alpha_0 - \alpha_{-1} + 2\epsilon} > 1,$$

and thus we can set

$$d = \min \left\{ \frac{\beta_0 - \alpha_{-1}}{\alpha_0 - \alpha_{-1} + 2\epsilon}, \frac{\beta_{-1} - \alpha_0}{\beta_{-1} - \beta_0 + 2\epsilon} \right\}.$$

□

Thus if a Birkhoff average diverges it must oscillate with at least exponentially increasing times. We now distinguish between those orbits which will exhibit behaviour **B1** and those which will exhibit behaviour **B2**. To this end for any $\gamma \in [\alpha_0, \beta_0]$ and $\epsilon > 0$ we will let $n_i = n_i(\gamma, \epsilon)$ be the subsequence of positive integers such that $B_{n_i} \in (\gamma - \epsilon, \gamma + \epsilon)$. Our main result will be the following.

Theorem 2.4. *Suppose that $B_n(x)$ has limit set $[\alpha_0, \beta_0]$.*

1. *If there exists $D > 1$ such that for all $\gamma \in [\alpha_0, \beta_0]$ and $\epsilon > 0$*

$$\frac{n_{i+1}(\gamma, \epsilon)}{n_i(\gamma, \epsilon)} \leq D \text{ for all } i \in \mathbb{N} \quad (2.2)$$

*then $B_n(x)$ is **B1**.*

2. *If for every $\gamma \in [\alpha_0, \beta_0]$ we can find $\epsilon > 0$ such that*

$$\limsup_{i \rightarrow \infty} \frac{n_{i+1}(\gamma, \epsilon)}{n_i(\gamma, \epsilon)} = \infty$$

*then $B_n(x)$ is **B2***

3 Proof of Theorem 2.4 and Other Results

Proposition 3.1. *Suppose that $\phi(x_i)$ is bounded, B_n diverges and there exists $1 < D < \infty$ such that*

$$\limsup_{j \rightarrow \infty} \frac{t_{j+1}(\epsilon)}{t_j(\epsilon)} \leq D, \quad (3.1)$$

for all $\epsilon > 0$ sufficiently small, then

$$\beta_0 - \alpha_0 \leq \frac{D-1}{D+1} (\beta_{-1} - \alpha_{-1}). \quad (3.2)$$

Proof:

Denote α_{-1} and β_{-1} as above and assume that n is large enough so that $\alpha_{-1} - \epsilon < \phi(x_i) < \beta_{-1} + \epsilon$ for all $i \geq n$. Suppose j is even so that $B_{t_j} < \alpha_0 + \epsilon$. Given any $\delta > 0$ we may assume that j is large enough so that $t_{j+1}/t_j < D + \delta$. Then we have

$$\begin{aligned} B_{t_{j+1}} - B_{t_j} &\leq \frac{1}{t_{j+1}} (t_j B_{t_j} + (t_{j+1} - t_j)(\beta_{-1} + \epsilon)) - B_{t_j} \\ &\leq \frac{t_{j+1} - t_j}{t_{j+1}} (\beta_{-1} + \epsilon - B_{t_j}) \\ &\leq \left(1 - \frac{1}{D + \delta}\right) (\beta_{-1} - \alpha_0). \end{aligned} \quad (3.3)$$

Thus we conclude that

$$\beta_0 - \alpha_0 \leq \frac{D-1}{D}(\beta_{-1} - \alpha_0).$$

Similarly, for j odd we calculate:

$$\beta_0 - \alpha_0 \leq \frac{D-1}{D}(\beta_0 - \alpha_{-1}).$$

Combining these inequalities we obtain (3.2). $\square$

Now consider higher order means. For $\{B_n\}$ we defined a sequence of times $\{t_j\}$ above. If j is even, recall that $B_{t_j} < \alpha_0 + \epsilon$ and $B_{t_{j+1}} > \beta_0 - \epsilon$. Define $t_j^{(1)}$ to be the index n , $t_j \leq n < t_{j+1}$, at which $H_n^{(1)}$ achieves its minimum. Also for j odd define $t_j^{(1)}$ to be the index n , $t_j \leq n < t_{j+1}$, at which $H_n^{(1)}$ achieves its maximum. Note that $H_n^{(1)}$ can achieve a local minimum or maximum only when its values and those of B_n cross.

For $k > 1$ we may define inductively times $\{t_j^{(k)}\}$ in a similar way as $\{t_j^{(1)}\}$. In particular we have:

$$\dots < t_{j-1}^{(k-1)} \leq t_{j-1}^{(k)} < t_j^{(k-1)} \leq t_j^{(k)} < t_{j+1}^{(k-1)} \leq t_{j+1}^{(k)} < \dots \quad (3.4)$$

The proof of the following proposition is similar to that of Proposition 3.1.

Proposition 3.2. *Suppose that $\phi(x_i)$ is bounded, B_n diverges and there exists $1 < D < \infty$ such that*

$$\limsup_{j \rightarrow \infty} \frac{t_{j+1}^{(k)}}{t_j^{(k)}} \leq D, \quad (3.5)$$

for some k and for all $\epsilon > 0$ sufficiently small, then

$$\beta_k - \alpha_k \leq \frac{D-1}{D+1}(\beta_{k-1} - \alpha_{k-1}). \quad (3.6)$$

Note however, that (3.1) does not imply (3.5), but the nesting (3.4) along with (3.1) imply that the limit supremum in (3.5) is less than D^{k+1} .

Next we consider type **B2** sequences. A specific case of type **B2** behavior is captured in the following.

Proposition 3.3. *If $\phi(x_i)$ is bounded, $\{B_n\}$ diverges and $[\alpha_0, \beta_0] = [\alpha_{-1}, \beta_{-1}]$ then $[\alpha_k, \beta_k] = [\alpha_{-1}, \beta_{-1}]$ for all k , so the Birkhoff averages are of type **B2**.*

Proof:

Since the limit set of $\{H^{(k)}\}$ is $[\alpha_k, \beta_k]$ it follows that for a given k and any $\epsilon > 0$ there exists $N(k, \epsilon)$ such that $\alpha_k - \epsilon < H_n^{(k)} < \beta_k + \epsilon$ for all $n > N(k, \epsilon)$.

Under the assumptions of the proposition, given any $\epsilon > 0$, the sequence B_n is greater than $\beta_{-1} - \epsilon$ infinitely often. Further, we may assume that n is sufficiently large so that $\phi(x_n) < \beta_{-1} + \epsilon$. Now given any $\delta > \epsilon$ suppose that:

$$B_n < \beta_{-1} - \delta \quad \text{while} \quad B_{n+i} > \beta_{-1} - \epsilon,$$

for some positive integer i . By the assumptions this must happen infinitely often. Since $\phi(x_n) < \beta_{-1} + \epsilon$ it follows that

$$B_{n+i} < \frac{1}{n+i} (n(\beta_{-1} - \delta) + i(\beta_{-1} + \epsilon)).$$

Since $B_{n+i} > \beta_{-1} - \epsilon$ we find from the preceding equation that

$$i > \frac{n(\delta - \epsilon)}{2\epsilon}.$$

If n is the last integer before B_j reaches a maximum but $B_n < \beta_{-1} - \delta$, then $B_j > \beta_{-1} - \delta$ for at least $i = n(\delta - \epsilon)/2\epsilon$ consecutive steps. This gives us that

$$\begin{aligned} H_{n+i}^{(1)} &= \frac{1}{n+i} \left(nH_n^{(1)} + \sum_{j=n+1}^{n+i} B_j \right) \\ &> \frac{1}{n+i} (n(\alpha_{-1} - \epsilon) + i(\beta_{-1} - \delta)) \\ &> \frac{2\epsilon}{\delta + \epsilon} (\alpha_{-1} - \epsilon) + \frac{\delta - \epsilon}{\delta + \epsilon} (\beta_{-1} - \delta). \end{aligned} \tag{3.7}$$

Since ϵ is taken arbitrarily small (by taking n large) $H_{n+i}^{(1)}$ is arbitrarily close to $\beta_{-1} - \delta$. Since δ is taken arbitrarily small, we conclude that $\beta_1 = \beta_{-1}$.

Assuming that $\overline{\lim}_{n \rightarrow \infty} H_n^{(k)} = \beta_{-1}$, by a similar calculation as above we can show that $\overline{\lim}_{n \rightarrow \infty} H_n^{(k+1)} = \beta_{-1}$, which proves the result. $\square$

Now we prove part 1 of Theorem 2.4. First note that if (2.2) holds for both $\gamma = \alpha_0$ and $\gamma = \beta_0$, then all j we have $\frac{t_{j+1}(\epsilon)}{t_j(\epsilon)} \leq D$.

Lemma 3.4. *If $\phi(x_i)$ is bounded, $\{B_n\}$ diverges and the Birkhoff averages are of type **B2**, then for any $k \geq 1$*

$$\limsup_{j \rightarrow \infty} \frac{t_{j+1}^{(k)}}{t_j^{(k)}} = +\infty. \tag{3.8}$$

Proof: By the assumptions there exists K such that

$$\alpha_k > \alpha_\infty - \frac{\epsilon}{2} \quad \text{and} \quad \beta_k < \beta_\infty + \frac{\epsilon}{2},$$

for all $k \geq K$. Note that $H_n^{(k)} > \beta_k - \epsilon/2$ for infinitely many n . Given $\delta > \epsilon$ suppose that

$$H_n^{(k)} < \beta_k - \delta \quad \text{and} \quad H_{n+i}^{(k)} > \beta_k - \frac{\epsilon}{2}.$$

Since $H_n^{(k-1)} < \beta_\infty + \epsilon$ for $k > K$ and n sufficiently large, we see that

$$H_{n+i}^{(k)} < \frac{1}{n+i} (n(\beta_k - \delta) + i(\beta_\infty + \epsilon)).$$

In order to have $H_{n+i}^{(k)} > \beta_k - \frac{\epsilon}{2}$ we calculate that i must satisfy:

$$i > \frac{n(\delta - \epsilon)}{2\epsilon}.$$

Let $t_j^{(k)}$ be the minimum point before n and $t_{j+1}^{(k)}$ be the maximum following n . We then have that

$$\frac{t_{j+1}^{(k)}}{t_j^{(k)}} > \frac{\delta - \epsilon}{2\epsilon}.$$

Since ϵ can be taken arbitrarily small the result follows for all $k > K$. The interlacing (3.4) of $\{t^{(k-1)}\}$ with $\{t^{(k)}\}$ implies the result for $k \leq K$. $\square$

This gives us a sufficient condition for **B1** behaviour.

Corollary 3.5. *Suppose that $\phi(x_i)$ is bounded, B_n diverges and there exists $1 < D < \infty$ such that*

$$\limsup_{j \rightarrow \infty} \frac{t_{j+1}}{t_j} \leq D, \quad (3.9)$$

*for all $\epsilon > 0$ sufficiently small, then the Birkhoff averages are of type **B1**.*

Proof:

Given the nested definition of the times in (3.4), we can conclude that

$$\limsup_{j \rightarrow \infty} \frac{t_{j+1}^{(1)}}{t_j^{(1)}} < D^2. \quad (3.10)$$

The result then follows from Lemma 3.4. $\square$

We can deduce part 1 of Theorem 2.4 from Corollary 3.5.

Next, let us consider part 2 of the Theorem. Recall our notation that $[\alpha_0, \beta_0]$ is the limit set for the sequence of Birkhoff averages B_n .

Lemma 3.6. *For any $\gamma \in [\alpha_0, \beta_0]$ if there exists an $\epsilon > 0$ such that*

$$\limsup_{i \rightarrow \infty} \frac{n_{i+1}(\epsilon, \gamma)}{n_i(\epsilon, \gamma)} = \infty, \quad (3.11)$$

then $\cap_{k=1}^{\infty} [\alpha_k, \beta_k]$ contains a point outside of $(\gamma - \frac{\epsilon}{2}, \gamma + \frac{\epsilon}{2})$. In particular $\cap_{k=1}^{\infty} [\alpha_k, \beta_k]$ cannot be the single point γ .

Proof. Fix $\gamma \in [\alpha_0, \beta_0]$. We define a sequence $\{t_i\}_{i \in \mathbb{N}}$ as follows

$$t_1 \epsilon - (\gamma - \alpha_0 + \epsilon) \geq \frac{(1 + t_1)3\epsilon}{4}$$

and for $n > 1$

$$t_n \epsilon \frac{2^{n-1} + 1}{2^n} - \left(1 + \sum_{i=1}^{n-1} t_i\right) \alpha_0 \geq \frac{2^n + 1}{2^{n+1}} \left(1 + \sum_{i=1}^n t_i\right) n \epsilon.$$

Fix $k \in \mathbb{N}$. Since 3.11 holds we can find infinitely many n_i such that $\frac{n_{i+1}}{n_i} \geq 1 + \sum_{j=1}^k t_j$. We now show that for any $1 \leq n \leq k$, the interval $[\alpha_n, \beta_n]$ must contain a point outside $(\gamma - \frac{\epsilon}{2}, \gamma + \frac{\epsilon}{2})$. For convenience we will assume that for each integer i and for each n between n_i and n_{i+1} , we have $B_n \geq \alpha + \epsilon$ (To handle the other case we switch inequalities and replace α_0 by β_0). We proceed by induction. To start with consider $H_j^{(1)}$ for $(n_i)(1 + t_1) \leq j < n_{i+1}$ we know that

$$jH_j^{(1)} - j\gamma \geq (t_1)(n_i)\epsilon + (j - n_i(1 + t_1))\epsilon - n_i(\gamma - \alpha_0 + \epsilon) > \frac{n_i(1 + t_1)3\epsilon}{4} + (j - n_i(1 + t_1))\epsilon$$

from which it follows that $H_j^{(1)} \geq \gamma + \frac{3\epsilon}{4}$. Assume that for $(n_i) \left(1 + \sum_{l=1}^{n-1} t_l\right) \leq j < n_{i+1}$ we have $h_j^{(n-1)} - \gamma \geq \frac{2^{n-1}+1}{2^n} \epsilon$ thus for $z \geq (n_i) \left(1 + \sum_{l=1}^n t_l\right)$ we know that

$$\begin{aligned} zH_z^{(n)} - z\gamma &\geq \left(z - n_i \left(1 + \sum_{l=1}^{n-1} t_l\right)\right) \frac{2^{n-1}+1}{2^n} \epsilon - n_i(\gamma - \alpha_0 + \epsilon) \left(1 + \sum_{l=1}^{n-1} t_l\right) \\ &= n_i t_n \epsilon \frac{2^{n-1}+1}{2^n} - \alpha_0 n_i \left(1 + \sum_{l=1}^{n-1} t_l\right) + \left(z - n_i \left(1 + \sum_{l=1}^n t_l\right)\right) \frac{2^{n-1}+1}{2^n} \epsilon \\ &\geq \frac{2^n+1}{2^{n+1}} \left(1 + \sum_{l=1}^n t_l\right) n_i \epsilon + \left(z - n_i \left(1 + \sum_{l=1}^n t_l\right)\right) \frac{2^{n-1}+1}{2^n} \epsilon \end{aligned}$$

and it follows that $H_z^{(n)} \geq \gamma + \frac{2^n+1}{2^{n+1}}$. The result now follows by induction. $\square$

Part 2 of Theorem 2.4 immediately follows.

4 Full Shift on Finite Symbols

4.1 Some Examples

Example 1. *A sequence whose orbit is type B1.*

Consider the sequence starting with 0, followed by 2 ones, followed by 2^2 zeros, followed by 2^3 ones, etc., i.e.

$$\{x_n\} = \{0, 1, 1, 0, 0, 0, 0, \underbrace{1, \dots, 1}_{2^3}, \underbrace{0, \dots, 0}_{2^4}, 1, \dots\}.$$

For this example, one may calculate directly that the limit set of B_n is $[1/3, 2/3]$. Let t_j be as above, then

$$\lim_{j \rightarrow \infty} \frac{t_{j+1}}{t_j} = 2 = d = D.$$

Thus, by Corollary 3.5 the orbit of this sequence is of type **B1**. We also observe that the estimate (3.2) is optimal.

Example 2. *A sequence whose orbit is of type B2.*

Consider the sequence beginning with 1 zero, followed by 2 ones, followed by 9 zeros, followed by 48 ones, etc., so that the i th group of constant x_n is i times as long as all the preceding groups put together. That is, the length ℓ_i of the i -th constant group is given recursively as:

$$\ell_1 = 1, \quad \ell_i = i \sum_{k=1}^{i-1} \ell_k, \text{ for } i \geq 2.$$

It is easily seen for this example that the limit set of B_n is $[0, 1]$. By Proposition 3.3 the sequence is of type **B2**.

Example 3. *An L^1 counterexample.* We can construct an unbounded L^1 function and a sequence for which the first Birkhoff averages do not converge but the second averages converge. Consider

the space $\{-1, 1\}^{\mathbb{N}}$ and let σ be the usual left shift. We define $f_1, f_2, f : \Sigma \rightarrow \mathbb{R}$ as follows

$$\begin{aligned} f_1(i) &= \inf\{n : i_{n+1} \neq i_1\}, \\ f_2(i) &= i_1, \\ f &= f_1 f_2. \end{aligned}$$

f is clearly L^1 with respect to any $(p, 1-p)$ Bernoulli measure but is not continuous since it blows up at $(1, 1, 1, \dots)$ and $(-1, -1, \dots)$.

Proposition 4.1. *For f and $j = (1, -1, -1, 1, 1, 1, -1, -1, -1, -1, \dots)$ the Birkhoff averages do not converge. However the average of the Birkhoff averages does converge.*

Proof: Let $k = n(n+1)/2$. If n is odd then

$$\sum_{m=0}^{k-1} f(\sigma^m j) = 1 - (1+2) + (1+2+3) - \dots + (1+2+3+\dots+n) = 1 + 3 + 5 + \dots + n.$$

If n is even then

$$\sum_{m=0}^{k-1} f(\sigma^m j) = 1 - (1+2) + (1+2+3) - \dots - (1+2+3+\dots+n) = -2 - 4 - 6 - \dots - n.$$

from which we can clearly deduce that the Birkhoff averages from f at j do not converge (note this does not use exponential times of oscillation but instead the fact that f is unbounded). In fact the averages oscillate between $-\frac{1}{2}$ when n is even and $\frac{1}{2}$ when n is odd.

Now we need to show that the average of the Birkhoff averages does converge. It is clear from the first part that the averages oscillate between $-\frac{1}{2}$ and $\frac{1}{2}$ subexponentially. By Proposition 2.3 the average of this sequence must converge.

□

4.2 Topological entropy

In a finite shift the set for which the averages do not converge is known to have full topological entropy or alternatively Hausdorff dimension (excluding the case when the function is cohomologous to a constant). A definition of topological entropy for non-compact sets was introduced in [1]. For further discussions see [11] and [2].

Let Σ be the full shift on m symbols and $f : \Sigma \rightarrow \mathbb{R}$ a continuous function which is not cohomologous to a constant. We will show that the set of points for which the Birkhoff averages are in class **B2** also has full topological entropy.

Proposition 4.2. *The set of points in class **B2** for f has topological entropy equal to $\log m$.*

Proof. Let ν be the evenly weighted Bernoulli measure and $\alpha = \int f d\nu$. Fix $\alpha_1 \neq \alpha_2 \in \mathbb{R}$ such that we can find two ergodic shift invariant probability measures μ_1, μ_2 such that $\int f d\mu_1 = \alpha_1$ and $\int f d\mu_2 = \alpha_2$. Choose $0 < \epsilon < \frac{\alpha_2 - \alpha_1}{4}$. Let X_N consist of sequences ω such that for all $n \geq N$

$$\left| \sum_{i=0}^{n-1} f(\sigma^i \omega) - n\alpha_1 \right| \leq n\epsilon$$

and

$$|\mu_1([i_1, \dots, i_n]) - nh(\mu_1)| \leq n\epsilon.$$

Similarly, let Y_n consist of sequences ω such that

$$\left| \sum_{i=0}^{n-1} f(\sigma^i \omega) - n\alpha_2 \right| \leq n\epsilon$$

and

$$|\mu_2([i_1, \dots, i_n]) - nh(\mu_2)| \leq n\epsilon.$$

Note that by the Birkhoff Ergodic Theorem and the Shannon-McMillan-Brieman Theorem [12, p. 93]

$$\lim_{N \rightarrow \infty} \mu_1(X_N) = 1 \text{ and } \lim_{N \rightarrow \infty} \mu_2(Y_N) = 1.$$

We now construct a new subset Z_N . We let $n_1 = N$ and $n_i = i \sum_{j=1}^{i-1} n_j$ for $i \geq 2$. We also let $k_i = \sum_{j \text{ odd}}^{2i-1} n_j$, $l_i = \sum_{j \text{ even}}^{2i} n_j$ be the sum of the odd and even n_i s and for convenience let $k_0 = l_0 = 0$. We define Z_n by the condition a sequence $\tau \in Z_n$ if and only if for each $i \geq 0$

1. $[\tau_{k_i+l_i+1}, \dots, \tau_{k_i+l_i+n_{2i+1}}] \cap X_N \neq \emptyset$
2. $[\tau_{k_{i+1}+l_{i+1}}, \dots, \tau_{k_{i+1}+l_{i+1}+n_{2i+2}}] \cap Y_N \neq \emptyset$.

Using the continuity of f and the definition of Z_n we can see that for any $\tau \in Z_n$ the limit set of the Birkhoff averages contains the interval $[\alpha_1 + \epsilon, \alpha_2 - \epsilon]$ and the condition for Proposition 3.3 are clearly satisfied. We now fix N large enough so that $\mu_1(X_N), \mu_2(Y_N) \geq \frac{1}{2}$. Thus we can estimate the growth of the number of n th level cylinders in Z_N . It is clear that for $n \geq N$

$$\begin{aligned} \#\{[\tau_1, \dots, \tau_n] : [\tau_1, \dots, \tau_n] \cap X_N \neq \emptyset\} &\geq \frac{1}{2} e^{n(h(\mu_1) - \epsilon)} \\ \#\{[\tau_1, \dots, \tau_n] : [\tau_1, \dots, \tau_n] \cap Y_N \neq \emptyset\} &\geq \frac{1}{2} e^{n(h(\mu_2) - \epsilon)}. \end{aligned}$$

Combining this with the definition of Z_n we can see that if we let M_n be the number of n th level cylinders containing elements of Z_n then

$$\liminf_{n \rightarrow \infty} \frac{\log M_n}{n} \geq \min\{h(\mu_1) - \epsilon, h(\mu_2) - \epsilon\}.$$

Thus we can define a measure ν by

$$\nu([\tau_1, \dots, \tau_n]) = \begin{cases} \frac{1}{M_n} & \text{if } [\tau_1, \dots, \tau_n] \cap Z_N \neq \emptyset \\ 0 & \text{if } [\tau_1, \dots, \tau_n] \cap Z_N = \emptyset \end{cases}$$

This measure will satisfy $\nu(Z_N) = 1$ and for any $\tau \in Z_N$ and n sufficiently large

$$\nu([\tau_1, \dots, \tau_n]) \leq e^{-n \min\{h(\mu_1) - \epsilon, h(\mu_2) - \epsilon\}}.$$

It follows by the entropy distribution principle (Theorem 3.6 in [11]) that

$$H(Z_n) \geq \min\{h(\mu_1) - \epsilon, h(\mu_2) - \epsilon\}.$$

To complete the proof we note that using results in [11] for any $\delta > 0$, by choosing α_1 and α_2 sufficiently close to α we can find measures μ_1 and μ_2 where $\log m - h(\mu_1) < \delta$, $\log m - h(\mu_2) < \delta$ and $\int f d\mu_1 = \alpha_1 \neq \int f d\mu_2 = \alpha_2$. $\square$

5 Bowen's example and a modification

5.1 Bowen's example is of type B1.

It is well known that in Bowen's example there is an open set of initial conditions whose orbits are historical, i.e. of type **B**. In this section we will recall Bowen's example and show that its orbits are in fact of type **B1**.

Let F^t be a flow possessing two hyperbolic equilibria $\mathbf{p}_1$ and $\mathbf{p}_2$ and a heteroclinic cycle as shown in Figure 1. Let the flow be symmetric under the transformations:

$$(u, t) \mapsto (-u, -t) \quad \text{and} \quad (v, t) \mapsto (-v, -t).$$

(This symmetry is not essential, but we assume it for clarity.) In this section we will use the Birkhoff average for the flow, which is defined as

$$B(x) = \lim_{t \rightarrow +\infty} \frac{1}{t} \int_0^t \phi(F^t(x)),$$

if it exists.

Suppose that $\phi(p_1) \neq \phi(p_2)$ and that the linearized flow at each of the two hyperbolic equilibria has eigenvalues

$$-\lambda < 0 < \mu,$$

and suppose

$$\rho = \frac{\lambda}{\mu} > 1.$$

so that all orbits in an interior neighbourhood of the heteroclinic cycle limit onto the cycle. Let U_1 and U_2 be small neighbourhoods of these points. It follows that the flow on these neighbourhood is C^1 linearizable. In the linearized coordinate the flow has the form:

$$\begin{aligned} \dot{x} &= \mu x \\ \dot{y} &= -\lambda y \end{aligned} \tag{5.1}$$

In fact we may choose the linearizing transformation $\Psi_i : (u, v) \mapsto (x, y)$ so that $\Psi_i : U_i \mapsto [0, 1] \times [0, 1]$ [13]. As interior orbits circulate toward the heteroclinic cycle, they spend more and more time near the equilibria and the average moves first toward $\phi(p_1)$ then toward $\phi(p_2)$. To be precise, the time of transition through U_1 or U_2 is

$$T_j = \frac{1}{\mu} \ln \frac{1}{x_j}$$

where x_j is the x coordinate at which the orbit enters one of the neighbourhoods for the j -th time. The orbit will then leave the neighbourhood with y -coordinate

$$y_j = x_j^\rho.$$

Now supposing that we begin with $x = x_0$ entering one of the neighbourhoods, then the transition times T_j are given by

$$T_j = C\rho^j$$

Figure 1: A symmetric heteroclinic cycle. Cross sections Σ^- and Σ^+ sweep out regions D_1 and D_2 . They also sweep out foliations of these regions which are used to define linearized coordinates.

where

$$C = \frac{1}{\mu} \ln \frac{1}{x_0}.$$

These results also follow from Gaunerdorfer [4] or Takens [9]. Thus, in Bowen's example

$$\lim_{j \rightarrow \infty} \frac{t_{j+1}}{t_j} = \rho,$$

and thus it follows from Corollary 3.5 that the behavior is of type **B1**. Another example involving non-hyperbolic fixed points with the same exponential growth as in Bowen's example was given in [13].

5.2 An modification of Bowen's example with B2 behavior.

Suppose that the equilibria, rather than being hyperbolic, have the following form locally:

$$\begin{aligned} \dot{x} &= x^3 \\ \dot{y} &= -\lambda y, \end{aligned} \tag{5.2}$$

on symmetric neighbourhoods in terms of charts that are given by $0 < x < d$, $0 < y < d$. Suppose that an orbit enters one of the two neighbourhoods for the j -th time at $x = x_j$ and $y = d$. The solution within the neighbourhood is given by:

$$x = \frac{1}{\sqrt{x_j^{-2} - 2t}}, \quad y = de^{-t}.$$

From this we calculate that the transition time T_j (when $x(t) = d$) for this crossing of the neighbourhood is

$$T_j = \frac{1}{2} \left(\frac{1}{x_j^2} - \frac{1}{d^2} \right).$$

It follows that the y -coordinate at which the orbit leaves the neighbourhood is:

$$y_j = d \exp \left(-\frac{1}{2} \left(\frac{1}{x_j^2} - \frac{1}{d^2} \right) \right).$$

The orbit will then enter the other neighbourhood at x -coordinate, x_{j+1} , given by

$$x_{j+1} \approx \alpha d \exp \left(-\frac{1}{2} \left(\frac{1}{x_j^2} - \frac{1}{d^2} \right) \right),$$

where α depends on the global flow. The corresponding transition time T_{j+1} is

$$\begin{aligned} T_{j+1} &= \frac{1}{2} \left(\frac{1}{x_{j+1}^2} - \frac{1}{d^2} \right) \\ &\approx \frac{\exp \left(-\frac{1}{2} \left(\frac{1}{x_j^2} - \frac{1}{d^2} \right) \right)}{2\alpha^2 d^2} - \frac{1}{2d^2} \\ &\approx \frac{e^{T_j}}{2\alpha^2 d^2} \end{aligned}$$

Thus for this example transition times T_j satisfy:

$$T_{j+1} \geq K e^{T_j},$$

where $K > 0$ is a constant that depends on the global flow. Since this growth of times is even larger than in Example 2 of §3, we conclude that for all k we have that $[\alpha_k, \beta_k]$ is equal to the closed interval bounded by $\phi(p_1)$ and $\phi(p_2)$. The example is thus of type **B2**.
